This report replaces an earlier report with the same number published in June 1987. We recently discovered that the wrong length was used in calculating the friction factor  $\sigma = \frac{\lambda L}{C}$ . This error has been corrected in the present report.

## ABSTRACT

Test results are presented for the following seals:

- (a) smooth, concentric seals at four clearances (static-test-data only),
- (b) smooth seals at three clearances,
- (c) hole-pattern-damper seals, six configurations, and
- (d) helically-grooved-stator seals, seven helix angles

All of the above seals are tested in a liquid Halon test facility at high Reynolds numbers. In addition, a helically-grooved-stator seal was tested in an air-seal test facility.

An analysis of the test results with comparisons to theoretical predictions supports the following conclusions:

- (a) For seals, the Hirs' friction-factor model is more restricted than had been through previously. Experimentally-derived-Hirs empirical coefficients apply for a reasonable Reynolds number range but are clearly a function of clearance. Further, there are significant differences between measured  $\lambda$  values with centered concentric seals and a seal with the rotor orbiting. Fortunately, the difference between concentric and orbiting-rotor friction factor data is reduced as the radial clearance is reduced.
- (b) For smooth seals, predictions of damping improve as the radial clearance is reduced.
- (c) For smooth seals, stiffness predictions are within 10% of measured values for  $C_r/R = .01, .0075$ ; however, for  $C_r/R = .005$ , stiffness is over predicted by approximately 20%.
- (d) Friction-factor data for hole-pattern-seal stators frequently deviates from the Hirs model.
- (e) Predictions of stiffness and damping coefficients for hole-pattern-stator seals is generally reasonable.
- (f) Test for the hole-pattern stators at reduced clearances (0.30 mm versus 0.51 mm) show no clear optimum for hole-pattern seals with respect to either hole-area ratio or hole depth to minimum-clearance ratios.
- (g) Tests of these hole-pattern stators show no significant advantage in net damping over smooth seals; however, the seals leak about 30% less than smooth seals.
- (h) Tests of helically-grooved seal stators in Halon show reasonable agreement between theory and prediction for leakage and direct stiffness but poor agreement for the net damping coefficient.
- (i) Tests of a helically-grooved stator in the air seal facility shows superior stability characteristics at high speeds (16,000 rpm) as compared of a honeycomb seal.

## Chapter I INTRODUCTION

The test and analysis results which are reported here were obtained under NASA Contract NAS8-35824. The present work continues research activity which began in January of 1980 under NASA Contract NAS8-33716. Earlier contract reports [3-7] provide detailed information covering the following points:

- (a) test-section and facility description,
- (b) test-objectives and procedures, and
- (c) data acquisition, analysis, and procedures.

Most of this information is not repeated here, and interested readers are referred to earlier reports.

From a rotordynamics viewpoint, seal analysis has the objective of predicting the coefficients for the following motion/reaction-force model

$$-\begin{Bmatrix} F_X \\ F_Y \end{Bmatrix} = \begin{bmatrix} K & k \\ -k & K \end{bmatrix} \begin{Bmatrix} X \\ Y \end{Bmatrix} + \begin{bmatrix} C & c \\ -c & C \end{bmatrix} \begin{Bmatrix} \dot{X} \\ \dot{Y} \end{Bmatrix} + M \begin{Bmatrix} \ddot{X} \\ \ddot{Y} \end{Bmatrix} \quad (1)$$

where  $X, Y$  are components of the seal-rotor displacement relative to its stator and  $F_X, F_Y$  are components of the reaction force. The diagonal and off-diagonal stiffness and damping coefficients are referred to, respectively, as "direct" and "cross-coupled". The cross-coupled coefficients arise due to fluid rotation within the seal. The coefficient  $M$  accounts for the seal's added mass.

If a circular orbit of the form

$$X = A \cos \omega t, \quad Y = A \sin \omega t \quad (2)$$

is assumed, Eq. (1) yields the following definition of force coefficients which are, respectively, parallel and perpendicular to the rotating displacement vector

$$\begin{aligned} F_r/A &= -K - c\omega + M\omega^2 \\ F_\theta/A &= k - C\omega \end{aligned} \quad (3)$$

Observe that the cross-coupled-stiffness coefficient  $k$  yields a "driving" tangential contribution in the direction of rotation, while the direct damping coefficient develops a drag force opposing the tangential velocity.

Recent test activities in this project have concerned "damper seal" configurations, which were largely inspired by von Pragenau's work [1]. Von Pragenau's analysis predicts that a smooth-rotor/rough-stator combination will yield a reduced asymptotic fluid tangential velocity within the seal, which will, in turn, yield a reduction in the cross-coupled stiffness coefficient. A reduced cross-coupled stiffness coefficient reduces the destabilizing

tangential driving force on the rotor, yields an increased net damping force, and generally enhances rotor stability and response. A subsequent and more comprehensive analysis by Childs and Kim [2] yields the same sort of encouraging predictions.

Reference [6] includes results for five new damper seal configurations including a round-hole-pattern stator similar to that illustrated in figure 1. The results for this seal configurations were encouraging, and a lengthy test series [7] was carried out which varied the following parameters:

(a) Hole-area density. This parameter is defined by

$$\gamma = \frac{\text{hole density}}{\text{total area}} \quad (4)$$

(b) Hole depth to minimum-clearance ratio,  $h/C_r$ .

The test results of reference [7] showed that an optimum value for net damping could be obtained for  $\gamma \cong 0.34$  and  $h/C_r \cong 3$ . All of the tests in references [6] and [7] were carried out with  $C_r = 0.51\text{mm}$  (.020 in), which corresponds to  $C_r/R = 0.01$ . By comparison, the interstage seals of the HPFTP operate at  $C_r/R = .0035$ . To examine the influence of a reduction in clearance, six additional hole-pattern stators were tested in the current program with  $C_r = 0.38\text{mm}$  (0.15 in).

Figure 1. Hole-pattern stator.

Kim and Childs [8] completed an analysis for helically-grooved seals during 1985 which indicated some distinct advantages, from a rotordynamic stability viewpoint, for properly-designed, helically-grooved seals versus smooth or hole-pattern damper stators. Tests were carried out on eight (8) helically-grooved stators in the present study to examine the correctness of these predictions.

The test apparatus used in this program does not control the inlet tangential velocity to the seal and provides no intentional fluid prerotation. Recent tests of honeycomb stators in an airseal test facility at TAMU has shown that honeycomb stators are clearly superior to smooth stators when the inlet air is prerotated in the direction of rotation, but are no better than smooth stators in the absence of fluid prerotation. Hence, one helically-grooved stator was manufactured and tested in the air-seal test facility.

The Hirs-based theory for damper seals [2] characterizes the shear stress at the rotor and stator in terms of empirical parameters which must be obtained from test data. The test data obtained from our test operations and used to calculate these parameters consists of the leakage rate, running speed, and axial pressure gradient. The procedure which has been used in this program to calculate the empirical coefficients has yielded erratic results. Hence, a new procedure is used to calculate the empirical coefficients for both hole-pattern stators and a smooth-stator/smooth-rotor seal at three different clearances.

In summary, the contents of this report cover the following topics:

- (a) analysis procedures for calculating Hirs' coefficients for rotor and stator surfaces with test results for four, smooth, centered seals,
- (b) static and dynamic test data for six additional hole-pattern stators,
- (c) static and dynamic test data for eight helically-grooved stators tested in the Halon test facility, and
- (d) static and dynamic test data for a smooth-rotor/smooth-stator seal at three different clearances.

## CHAPTER II

### HIRS' COEFFICIENT CALCULATIONS FROM STATIC TEST DATA FOR DAMPER AND SMOOTH SEALS

#### 2.1 Introduction

Figure 2 illustrates the liquid-seal test rig used in this study. Dynamic force coefficients represent the principal output of the apparatus; however, static test data are obtained during testing and consist of the following parameters:

- (a) leakage rate,
- (b) static pressure measurements near the entrance and exit and along the seal, and
- (c) running speed.

The balance of this chapter explains how these data are used to calculate the empirical coefficients used in Hirs' turbulent lubrication model [9].

### HIGH REYNOLDS NUMBER SEAL TEST SECTION

Figure 2. High-Reynolds-Number Seal Test Section.

## 2.2 Hirs' Turbulent Lubrication Model

A differential fluid element, with upper and lower surfaces corresponding to the rotor and stator surfaces respectively, is shown in Figure 3.

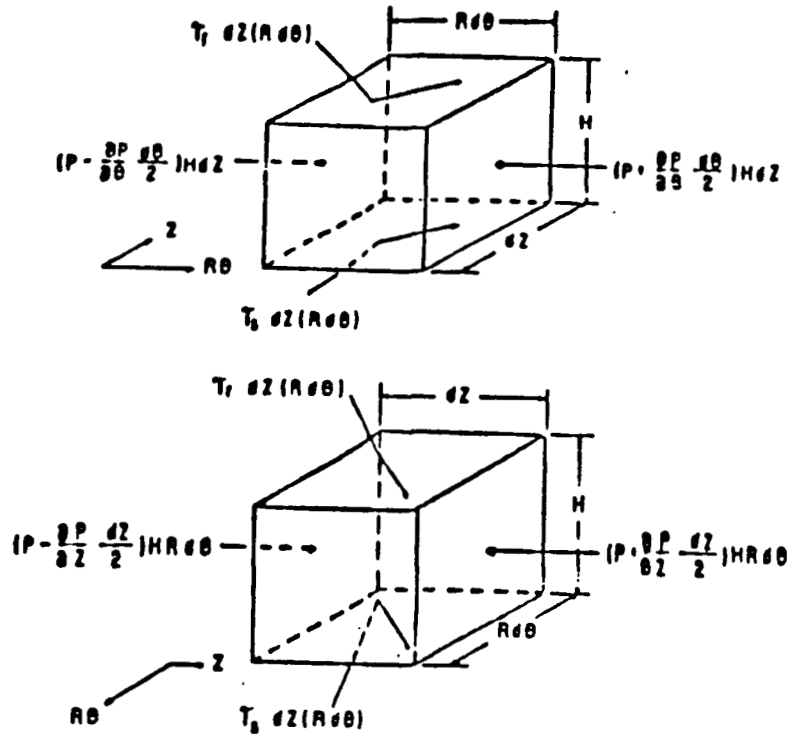

Figure 3. Differential fluid element for Hirs' bulk-flow model.

The bulk fluid velocities, which are averages across the film height  $H(\theta, z)$  of the axial and circumferential fluid velocities, are  $U_z$  and  $U_\theta$ . Hirs' turbulence formulation is based on an empirical function for the wall shear stress,  $\tau_w$ , of the form

$$\tau_w = \rho \frac{V_w^2}{2} n_o R^{m_o}$$

where  $R$  is the Reynolds number defined by

$$R = \frac{2\rho V_w H}{\mu}$$

and  $V_w$  is the average bulk-flow velocity relative to the wall. For the same surface roughness on the stator and rotor surface, the empirical coefficients  $m_o$  and  $n_o$  apply to both surfaces. For different surface roughnesses on the rotor and stator, the wall shear stresses are respectively

$$\tau_r = \rho \frac{V_r^2}{2} n_r \left( \frac{2\rho V_r H}{\mu} \right)^{mr} \quad (5)$$

$$\tau_s = \rho \frac{V_s^2}{2} n_s \left( \frac{2\rho V_s H}{\mu} \right)^{ms}$$

$V_r$  and  $V_s$  are the bulk flow velocities relative to the rotor and stator walls defined by

$$V_r = (U_\theta - R\omega)\epsilon_\theta + U_z\epsilon_z$$

$$V_s = U_\theta\epsilon_\theta + U_z\epsilon_z$$

Using the above definitions for the shear-stress, governing equations consisting of axial and circumferential momentum equations are developed. The bulk flow continuity equation completes the governing equations.

The governing equations define the bulk-flow velocity components and the pressure as functions of the spatial variables,  $R\theta$  and  $Z$ , and the time. Using a perturbation technique the nondimensional variables of these equations ( $u_z, u_\theta, p$  and  $h$ ) are expanded into zeroth-order and first-order equations. The zeroth-order equations can be solved for steady-state leakage, velocity fields, and the pressure field. The first-order equations define the rotordynamic coefficients.

For a constant clearance seal, the nondimensional zeroth-order equations are

$$\begin{aligned} \frac{dp_o}{dz} &= -(a_{os}\sigma + a_{or}\sigma_r)/2 \\ \frac{du_{\theta o}}{dz} &= [a_{os}\sigma_s u_{\theta o} + a_{or}\sigma_r(u_{\theta o} - 1)] \end{aligned} \quad (6)$$

where

$$\begin{aligned} a_{os} &= \left[ \frac{1 + (u_{\theta o}/bu_{zo})^2}{1 + (1/4b^2)} \right]^{\frac{ms+1}{2}} \\ a_{or} &= \left[ \frac{1 + (u_{\theta o}-1)/bu_{zo}^2}{1 + (1/4b^2)} \right]^{\frac{mr+1}{2}} \end{aligned}$$

Since the zeroth-order equations are coupled and nonlinear their solution is iterative. The initial conditions for these two nonlinear equations are

$$\begin{aligned} p(0) &= \Delta P / \rho V^2 \\ u_{\theta o}(0) &= U_{\theta o}(0) / R\omega \end{aligned} \quad (7)$$

### 2.3 Empirical Turbulence Coefficients.

The analysis of Childs and Kim [2] characterizes the surface roughness of the stator and rotor in terms of empirical coefficients ( $n_s, m_s, n_r, m_r$ ). These are the same coefficients that appear in Eq. 5, and they must be determined from static test data before the theoretical predictions can be made for  $F_r/A$  and  $F_\theta/A$ . The coefficients can be calculated in the following manner.

The steady-state axial pressure gradient can be stated as

$$\frac{dP_o}{dz} = -\sigma\rho V^2$$

Leakage is measured in the test apparatus, and the static pressure is measured at five axial locations. Averages of the measured upstream and downstream temperature and pressure are used to define the density. Hence, the parameter  $\sigma$  can be determined from known values for the density, axial velocity, and the measured pressure gradient. The pressure gradient is determined from a curve fit of the three middle pressure locations so entrance and exit effects do not significantly influence the calculation. The three locations are at approximately 20, 50, and 80 percent of the seal length. For a rough-stator/smooth-rotor combination this value is  $\sigma_c$ , which is related to the stator,  $\sigma_s$ , and rotor,  $\sigma_r$ , by

$$\sigma_c = \frac{\sigma_r + \sigma_s}{2} \quad (8)$$

The  $\sigma$  parameters are related to the friction factor,  $\lambda$ , by

$$\sigma_r = \lambda_r \frac{L}{C_r}, \sigma_s = \lambda_s \frac{L}{C_r}, \quad (9)$$

and the friction factor is related to the empirical coefficients through the following friction-factor formulas

$$\lambda_r = n_r R_a^{m_r} [1 + ((u_{\theta o} - 1)/b)^2]^{\frac{m_r + 1}{2}} \quad (10)$$

$$\lambda_s = n_s R_a^{m_s} [1 + (u_{\theta o}/b)^2]^{\frac{m_s + 1}{2}} \quad (11)$$

where

$$R_a = \frac{VC\rho}{\mu}, \quad b = V/R\omega$$

This leads to the following problem which must be resolved: given measured data sets ( $R_{a_i}, \omega_i, \lambda_i$ ), determine the values for  $m_r, n_r, m_s$ , and  $n_s$  from Eqs. (10) and (11).

The tangential velocity component,  $u_\theta$ , of Eqs. (10) and (11) is generally a function of the axial position  $z$ . In previous analyses,  $u_\theta$  has been set equal to one half, the asymptotic value for seals with equal rotor and stator roughnesses. For the present analysis,  $u_\theta$  is set equal to the average nondimensional circumferential velocity

$$\bar{u}_{\theta o} = \int_0^1 u_{\theta o}(z) dz \quad (12)$$

where  $u_{\theta o}(z)$  is the solution of the zeroth-order equations. Hence Eqs. (10) and (11) become

$$\lambda_r = n_r R_a^{m_r} [1 + ((\bar{u}_{\theta o} - 1)/b)^2]^{\frac{m_r+1}{2}} \quad (13)$$

$$\lambda_s = n_s R_a^{m_s} [1 + (\bar{u}_{\theta o}/b)^2]^{\frac{m_s+1}{2}} \quad (14)$$

Since the solution of the zeroth-order equations for  $u_{\theta o}$  and  $p_o$  depend on  $m_r, n_r, m_s$ , and  $n_s$ , the solution is iterative. A value must be assumed for  $u_{\theta o}(0)$  to begin the iterative solution procedure. Once this value is assumed, first approximations for  $m_r, n_r, m_s$ , and  $n_s$  can be calculated from Eqs. (13) and (14). Experience shows that for the present apparatus,  $u_{\theta o}(0) = 0.1$  is an adequate approximation.

For a smooth stator and smooth rotor the same coefficients apply for both rotor and stator; hence,  $m_s = m_r$ , and  $n_s = n_r$ , so  $n_r$  and  $n_r$  can be found from the smooth-rotor/smooth-stator data. The parameter-identification procedure is slightly different when both surfaces have the same roughness, as apposed to the smooth rotor/rough stator combination, and a more detailed explanation of this problem is provided below.

From Eq. (8)

$$\sigma_c = \frac{L}{2C_r} (\lambda_r + \lambda_s) = \frac{L}{2C_r} \bullet \lambda_c \quad (15)$$

For the same roughness on both surfaces, the empirical coefficients  $n = n_r = n_s, m = m_r = m_s$ , and Eq. (15) can be stated

$$2\sigma_c \frac{C_r}{L} = 2\lambda_c = n(C_1 X^m + C_2 Y^m) \quad (16)$$

where

$$C_1 = [1 + ((u_{\theta o} - 1)/b)^2]^{1/2}$$

$$C_2 = [1 + (u_{\theta o}/b)^2]^{1/2}$$

(17)

$$X = R_a C_1, Y = R_a C_2,$$

This form of the governing equations isolates the unknown coefficients  $m$  and  $n$ .

If the circumferential velocity  $u_{\theta o}$  is assumed to be the asymptotic value,  $1/2, C_1 = C_2, X = Y$ , and a linear curve fit of the log form of Eq.(16) yields  $\ln(n)$  and  $m$ . However,

if  $u_{\theta o} \neq 1/2$ ,  $C_1 \neq C_2$ , and performing the logarithm of Eq. (16) is not helpful in reducing the problem.

In the following procedure,  $u_{\theta o}$  is set equal to  $\bar{u}_{\theta o}$  in Eq. (17). The parameters  $m$  and  $n$  are defined by minimizing the following objective function

$$E = \sum_{i=1}^k (2\lambda_{ci} - 2\hat{\lambda}_{ci})^2 = \sum_{i=1}^k [n(C_{1i}X_i^m + C_{2i}Y_i^m) - 2\hat{\lambda}_{ci}]^2 \quad (18)$$

which is the summation over the  $k$  data points of the squared difference between the predicted,  $\lambda_{ci}$ , and the measured,  $\hat{\lambda}_{ci}$ , friction factors. Minimization of  $E$  with respect to  $m$  and  $n$  yields the following equations

$$f = \frac{\partial E}{\partial n} = \sum_{i=1}^k [n(C_{1i}X_i^m + C_{2i}Y_i^m) - 2\hat{\lambda}_{ci}](C_{1i}X_i^m + C_{2i}Y_i^m) = 0 \quad (19)$$

$$g = \frac{\partial E}{\partial m} = \sum_{i=1}^k [n(C_{1i}X_i^m + C_{2i}Y_i^m) - 2\hat{\lambda}_{ci}]n(C_{1i}X_i^m \ln X_i + C_{2i}Y_i^m \ln Y_i)m = 0$$

These nonlinear equations are solved for  $n$  and  $m$  using a Newton-Raphson procedure. Figure 4 provides a flowchart for the solution algorithm used to obtain  $n$  and  $m$  for equal rotor and stator roughnesses. An iterative solution is required since the differential equations (6) include the unknown parameters  $n$  and  $m$ , and Eq. (19) contains  $C_1$  and  $C_2$  which depend on  $\bar{u}_{\theta o}$ .

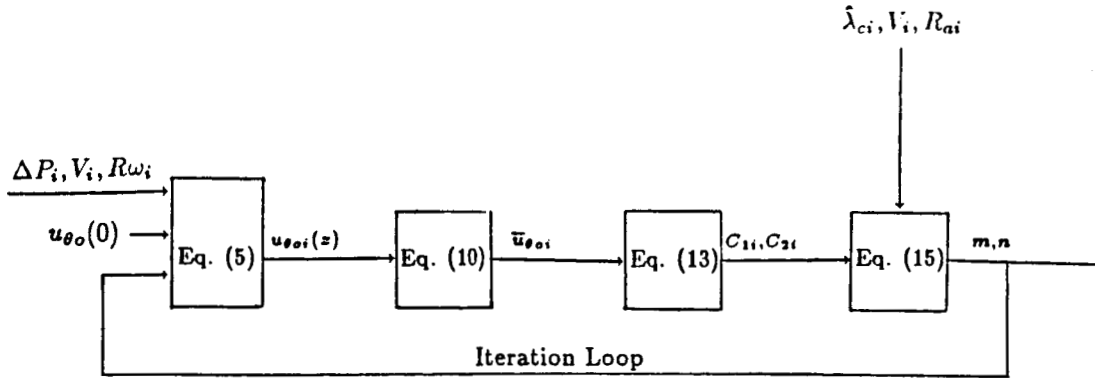

Figure 4. Flowchart for the solution of the empirical coefficients for equal rotor and stator surface roughnesses. The subscript  $i$  denotes the  $i$ th data point.

In the present investigation, the empirical coefficients  $m$ s and  $n$ s are to be calculated for various surface roughened stators assuming that values for  $m_r$  and  $n_r$  are known for the rotor. The values for  $m_r$  and  $n_r$  are obtained from Eq. (19) from tests of seals with

smooth rotors and stators. The flowchart of figure 5 illustrates the solution procedure for this problem. The upper portion of this figure shows the calculation of  $\lambda_{ri}$  from Eq. (13). Eq. (15) is then used to subtract  $\lambda_{ri}$  from the measured combined seal friction factor  $\lambda_{ci}$  to obtain a value for  $\lambda_{si}$ . For a given data point, Eq. (14) can be restated as

$$Z_i = 1n(n_s) + m_s X_i$$

where

$$Z_i = 1n \left( \frac{\lambda_{si}}{[1 + (\bar{u}_{\theta oi}/b_i)^2]^{1/2}} \right)$$

$$X_i = 1n(R_a[1 + (\bar{u}_{\theta oi}/b_i)^2]^{1/2})$$

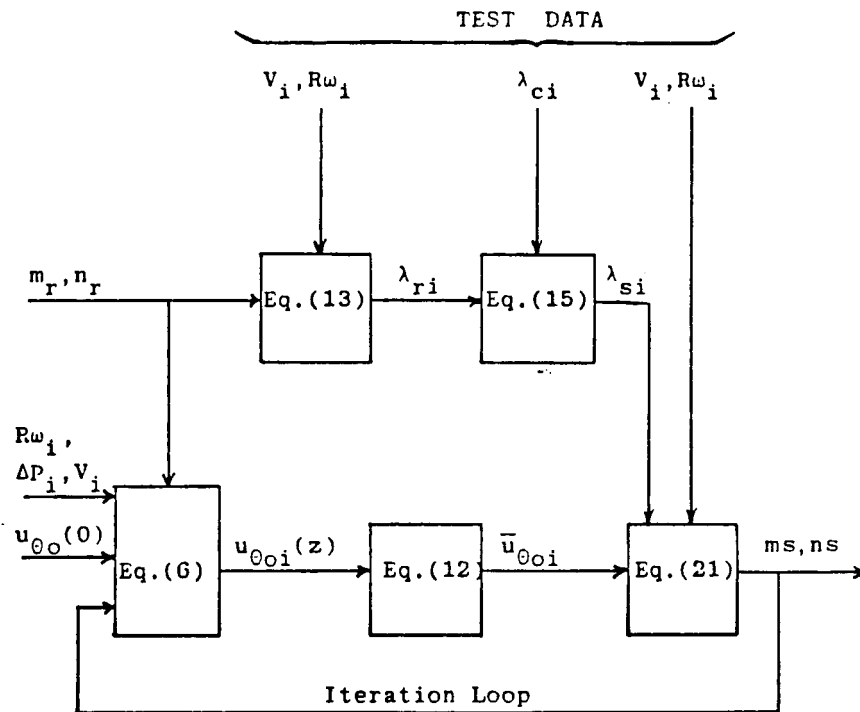

Figure 5. Flowchart for the solution of stator empirical turbulence coefficients  $m_s, n_s$  from test data and known rotor coefficients. The subscript  $i$  denotes the  $i$ th data point

The objective function to be minimized with respect to  $1n(n_s)$  and  $m_s$  is

$$E = \sum_{i=1}^k (Z_i - \hat{Z}_i)^2$$

where  $Z_i$  and  $\hat{Z}_i$  are the measured and predicted values for  $Z_i$  respectively. A least-square curve fit of this relationship yields the following equations

$$\left[ \begin{array}{c} k \\ \sum_{i=1}^k X_i \\ \sum_{i=1}^k X_i \sum_{i=1}^k X_i^2 \end{array} \right] \left\{ \begin{array}{c} 1n(n_s) \\ m_s \end{array} \right\} = \left\{ \begin{array}{c} \sum_{i=1}^k \hat{Z}_i \\ \sum_{i=1}^k X_i \hat{Z}_i \end{array} \right\} \quad (20)$$

#### 2.4 Friction Factor and Empirical-Coefficient Results for Smooth, Centered Seals.

Four smooth stators were manufactured and tested in the apparatus of figure 2 solely to obtain friction-factor versus leakage data. The test rotor was run at speeds from 1000 to 7200 rpm; however, the seal elements of the rotor had no eccentricity, unlike the dynamic tests with eccentric rotors which are reported in subsequent chapters. The stators all had measured surface roughnesses of approximately  $0.81\mu m$ . The seals were tested at the following clearances: (a) .312 mm, (b) .375 mm, (c) .446 mm, and (d) .500 mm. Figure 6 illustrates test and theoretical results for  $\lambda$  as a function of running speed and Reynolds number. The theoretical results of figure 6 are based on calculated  $m$ ,  $n$  values which were obtained from the solution procedure of figure 4. An inspection of these figures shows a generally good agreement between experiment and theory. A summary of the  $m$ ,  $n$  results is provided in Table 1.

$C_r(mm)$	$D(mm)$	$m$	$n$	$R_a(max)$
0.312	101.00	-.206	.1	250,000
0.375	100.85	-.058	.0106	360,000
0.446	100.71	-.139	.0434	360,000
0.508	100.58	-.114	.0222	475,000

Table 1. Hirs Coefficients for  $0.81\mu m$  roughness.

These data indicate that the empirical parameters  $m$ ,  $n$  can only characterize the friction-factor properties of the stator for the same clearance, roughness, and Reynolds-number range. The data can also be interpreted in terms of changes in relative roughness,  $\epsilon = e/2C_r$ , where  $e$  is the absolute roughness. As the clearance is reduced  $e$  remains fixed; however,  $\epsilon$  increases. These results support the use of a Moody friction-factor characterization as proposed by Nelson and Nguyen [9] rather than a Hirs-based analysis.

# **CHAPTER III** **STATIC AND DYNAMIC TEST RESULTS** **FOR NOMINALLY SMOOTH SEALS** **WITH THREE DIFFERENT RADIAL CLEARANCES**

## **3.1 Introduction**

As noted previously, a substantial portion of this study involved testing hole-pattern damper seals at reduced radial clearances. As will be discussed in the following chapter, these tests showed some unexpected results; hence, the decision was made to test a nominally smooth seal ( $0.81\mu m$ ) at the following three radial clearances: 0.254, 0.381, and 0.508 mm. For all tests, the radial eccentricity was set at  $89\mu m$ . Test results for these seals are presented below.

## **3.2 Friction-Factor Data**

Figure 7 illustrates  $\lambda$  versus  $R_a$  and running speed for the seal at three different clearances. Observe that  $\lambda$  decreases monotonically with  $R_a$  and increases with running speed. The Hirs' coefficients for these three seal clearances are provided in table 2.

$C_r(mm)$	$m$	$n$	$R_a(max)$
0.254	-0.256	0.174	190,000
0.381	-0.098	0.0191	350,000
0.508	-0.056	0.0164	450,000

Table 2. Hirs coefficients for  $0.81\mu m$   
roughness seals with an eccentric rotor;  
seal diameter  $101.6mm$

The data of table 2 agree "reasonably" well with the data of table 1 for which the rotor is concentric.

## **3.3 Leakage Data**

Leakage data are presented in terms of the discharge coefficient definition

$$\Delta P = C_d \frac{\rho V^2}{2}$$

which yields

$$\dot{Q} = 2\pi R C_r V = \left(\frac{C_r}{R}\right) C_d^{-1/2} \cdot 2\pi R^2 \sqrt{\frac{2\Delta P}{\rho}} = C_L \cdot 2\pi R^2 \sqrt{\frac{2\Delta P}{\rho}} \quad (21)$$

Hence,

$$C_L = \left(\frac{C_r}{R}\right) C_d^{-1/2} = \dot{Q} / \left(2\pi R^2 \sqrt{\frac{2\Delta P}{\rho}}\right) \quad (22)$$

SMOOTH SEAL 0.254 mm cr.

SMOOTH SEAL 0.381 mm cr.

SMOOTH SEAL 0.508 mm cr.

Figure 7. Measured and theoretical values for  $\lambda$  versus Reynolds number and running speed for seals with a smooth stator and a smooth eccentric rotor;  $C_r = 0.254, 0.381, 0.508 \text{ mm}$ .

Seal-leakage data may be presented in terms of either  $C_d^{-1/2}$  or  $C_L$ . Figure 8 illustrates both these parameters as a function of  $\Delta P$ . Observe that  $C_L$  increases linearly with increasing  $C_r$ ; however,  $C_d^{1/2}$  first increases and then decreases as  $C_r$  increases.

### 3.4 Dynamic Test Data

Figure 9 illustrates measured and theoretical results for  $F_r/A$  and  $F_\theta/A$  versus  $R_a$  and  $\omega$  for the 0.254mm radial-clearance seal. The measured results are taken from table B.1, while the theoretical results are calculated using the analysis of [2] with the empirical parameters of table 2. An inspection of these results demonstrates a "reasonable" agreement between theory and experiment with respect to the tangential force but larger measured radial-force-coefficients magnitudes at low speeds than predicted. Further, the magnitude of  $F_r/A$  decreases more rapidly with increasing running speed than predicted. Figures 10 and 11 illustrate measured and theoretical predictions for the two remaining smooth seals.

Eq. (3) provides the basis for a quantitative comparison of theory and experiment. At first glance these equations suggest that sufficient independent equations could be obtained to calculate all the rotordynamic coefficients by simply testing at three running speeds. However, the fact that the coefficients depend on  $\omega$  precludes this approach. While  $K$ ,  $C$ , and  $M$  are weak functions of  $\omega$  through their dependence on  $\sigma$ , the "cross-coupled" coefficients  $k$  and  $c$  are linear functions of  $\omega$ . In fact, if the fluid is prerotated prior to entering the seal such that the inlet tangential velocity is  $U_{\theta 0} = R\omega/2$ , then theory predicts that  $k = C\omega/2$ ,  $c = -C\omega/2$ ,  $c = M\omega$ , and

$$F_r/A = -K, F_\theta/A = -C\omega/2 \quad (23)$$

The present test apparatus provides no intentional prerotation, and the expected result is of the form

$$k = b_1 C\omega/2, b_1 < 1 \quad (24)$$

$$c = b_2 M\omega, b_2 < 1$$

$$F_\theta/A \cong -C_{ef}\omega = -C(1 - b_1/2)\omega \quad (25)$$

$$F_r/A \cong K_{ef} + M_{ef}\omega^2 = -K + M(1 - b_2)\omega^2$$

The term  $C_{ef}$  denotes the "net damping coefficient" resulting from the drag force  $C\omega A$  and the forward whirl excitation force  $kA$ . A direct comparison between theory and experiment is obtained by curvefitting the theoretical and experimental results for the  $F_r/A$  and  $F_\theta/A$  data to obtain predictions for  $K_{ef}$ ,  $C_{ef}$ , and  $M_{ef}$ . Note that the procedure of curvefitting the data with respect to  $\omega$  eliminates the running-speed dependency. Further,  $K_{ef}$  is the zero-running speed intercept of the  $F_r/A$  versus  $\omega$  curve, and  $C_{ef}$  is the slope of the  $F_\theta/A$  versus  $\omega$  curve.

Figure 11. Measured and theoretical [2] results for  $F_r/A$  and  $F_\theta/A$ ; smooth seal,  $C_r = 0.508mm$ .

Experimentally-determined values are presented in table 3 for  $K_{ef}$ ,  $C_{ef}$ , and  $M_{ef}$ . A comparison of theoretical and experimental results is also presented in these tables. Observe that the seals are generally stiffer than predicted at the large clearances but less stiff for the smallest clearance. The correlation for  $C_{ef}$  worsens as  $R_a$  increases, but rapidly approaches an asymptote. The "correlation" for  $M_{ef}$  is too erratic to comment on except to note that measured  $M_{ef}$  values are generally much larger than predictions.

Table 3. Measured values for  $K_{ef}$ ,  $C_{ef}$ , and  $M_{ef}$ ; comparison of theory and experiment for smooth seals at three difference clearances.

The parameter  $K_{ef}$  can be normalized as follows

$$\overline{K}_{ef} = K_{ef} \left( \frac{C_r}{DL\Delta P} \right), \quad (26)$$

while  $C_{ef}$  can be similarly normalized as

$$\overline{C}_{ef} = C_{ef} \left( \frac{C_r}{DL\Delta P} \right), \quad (27)$$

or nondimensionalized as

$$\hat{C}_{ef} = C_{ef} \left( \frac{C_r T}{DL\Delta P} \right), \quad (28)$$

where  $T = L/V$  is the transit time for flow through the seal.

Figure 12 illustrates  $K_{ef}$  and  $\bar{K}_{ef}$  versus  $\Delta P$ . Observe that  $K_{ef}$  increases monotonically as  $C_r$  is reduced, and that the nondimensionalized parameter  $\bar{K}_{ef}$  generally collapses the test data into a narrow band. Hence the nondimensionalization is effective.

Figure 13 illustrates  $C_{ef}$  versus  $\Delta P$  for three different clearances. Observe that  $C_{ef}$  increases monotonically as  $\Delta P$  increases and  $C_r$  increases. The objective of a nondimensionalization for  $C_{ef}$  would be to reduce the three curves of figure 13 into a straight line, independent of both  $C_r$  and  $\Delta P$ . Figure 14 illustrates both the normalized parameter  $\bar{C}_{ef}$  and nondimensionalized parameter  $\hat{C}_{ef}$ . Observe that the normalization which yields  $\bar{C}_{ef}$  pulls the three curves into a tight band, largely eliminating the clearance dependency; however,  $\bar{C}_{ef}$  is now a decreasing function of  $\Delta P$ . The nondimensionalization which yields  $\hat{C}_{ef}$  eliminates the pressure dependency but leaves a dependency on  $C_r$ ; i.e., the  $C_r = 0.254mm$  curve is significantly displaced from the remaining two curves.

### 3.5 Conclusions

The test results presented here support the following conclusions:

- (a) The friction-factor data demonstrate that the Hirs' wall-friction model is considerably more restricted than had previously been thought. The empirical coefficients only characterize the seal surfaces at a fixed clearance and over a restricted Reynolds number range. The "Moody" approach of von Pragenau and Nelson and Nguyen needs to be examined to see whether it yields broader ranges of applicability.
- (b) The agreement between theory and experiment for  $C_{ef}$  is reasonable for all cases and improves as  $R_a$  increases and  $C_r$  decreases.
- (c)  $K_{ef}$  is slightly underpredicted for  $C_r/R = 0.01$  and  $0.075$ ; it is overpredicted by approximately 20% for  $C_r/R = 0.005$ .

# **CHAPTER IV** **TEST RESULTS FOR ROUND-HOLE** **PATTERN DAMPER SEALS AT REDUCED CLEARANCE**

## **4.1 Introduction**

Figure 15 illustrates the round-hole-pattern stator configurations which were tested in this contract phase. All seals were tested at 0.381mm radial clearances versus earlier tests at 0.51mm. The first four stators have  $\gamma = 0.34$ , which proved to be optimum in earlier test results, with a variation in  $h/C_r$  from 1.00 to 4.03. These tests include  $h/C_r = 2.92$ , which was the optimum result in our earlier tests. The parameter  $h/C_r$  is held constant for seals 5 and 6 while  $\gamma$  is changed to 0.27 and 0.42, respectively.

DIMENSIONS IN MILLIMETERS

Figure 15. Round-hole-pattern and stator configuration detail A.

#### 4.2 Friction-Factor Data

Figures 16 through 18 present measurements and predictions of  $\lambda_c$  versus  $R_a$  and  $\omega$  for test seals with the six hole-pattern stators. Recall from Eq. (18) that the  $\lambda_c$  values are obtained from measured, axial-pressure gradients and are assumed to be the average of  $\lambda_r$  (rotor) and  $\lambda_s$  (stator). The curves in these figures are generally similar to those obtained earlier for smooth seals. As expected,  $\lambda_c$  values are consistently higher for the rougher, round-hole-pattern stators. Note that the test results for  $\gamma = 0.42$  are markedly different from the remaining test data, with much greater speed sensitivity. Also note for this figure that at low speeds  $\lambda_c$  increases with  $R_a$ . At higher values of  $R_a$ ,  $\lambda_c$  decreases with increasing  $\omega$ .

Except for the  $\gamma = 0.42$  results, there is generally good agreement between  $\lambda_c$  measured and  $\lambda_c$  predicted in figures 16 through 18; however, this masks a significantly greater discrepancy between predictions and measurements for  $\lambda_s$ . Recall from chapter II that "experimental data" for  $\lambda_s$  are derived from measured values for  $\lambda_c$  and predicted values for  $\lambda_r$ . The predicted values for  $\lambda_r$  are based on values of  $m_r$ ,  $n_r$  which are obtained from separate pressure-gradient measurements in seals with the same smooth rotor and stator surfaces. Figures 19 through 21 compare "derived" and predicted values for  $\lambda_s$ . Note that the correlation between theory and derived data are generally not very good. Test results show much greater sensitivity to speed than the derived data. Also the derived data show  $\lambda_s$  decreasing with increasing speed at higher values for  $R_a$ , while the theory shows the opposite trend. Several of the lower-speed data curves show  $\lambda_s$  increasing with  $R_a$  instead of decreasing.

Table 4 presents calculated values for  $m_s$  and  $n_s$  for the six hole-pattern stators.

Stator	$m_s$	$n_s$	$R_a(max)$
1	-0.0481	0.0322	242,120
2	-0.1087	0.0739	233,560
3	0.0086	0.0208	236,570
4	-0.0747	0.0483	240,140
5	-0.0433	0.0312	260,600
6	0.0599	0.0127	253,980

Table 4. Hirs coefficients for hole-pattern stators  
as calculated using the solution approach of figure 5.

#### 4.3 Leakage Data

Figure 22 presents  $C_d^{-1/2}$  for the six hole-pattern stators. Observe that there is very little difference in the leakage performance of the seals using these stators. Minimum leakage results are obtained for  $(h/C_r = 1.0, \gamma = 0.34)$  and  $(h/C_r = 2.92, \gamma = 0.42)$ .

#### 4.4 Dynamic Test Data

Figures 23 through 28 provide comparisons between measured and theoretical values for  $F_r/A$  and  $F_\theta/A$  versus  $R_a$  and  $\omega$ . As with smooth seals, the prediction for  $F_\theta/A$  is generally better than  $F_r/A$ .

Figure 20. Stator lambda data for hole-pattern-stators 3 and 4.

Figure 21. Stator lambda data for hole-pattern-stators 5 and 6.

Figure 22.  $C_d^{-1/2}$  for hole-pattern-stator seals.

Figures 29 and 30 illustrate  $K_{ef}$  and  $\overline{K}_{ef}$  for the hole-pattern stators. For the  $\gamma = 0.34$  stators, the largest overall stiffness values result for  $h/C_r = 2.92$ . For the  $h/C_r = 2.92$  data, the  $\gamma = 0.27$  stator yields the maximum  $K_{ef}$  at high Reynolds numbers.

Figures 31 and 32 illustrate  $C_{ef}$  and  $\overline{C}_{ef}$  for the hole-pattern stators. For the  $\gamma = 0.34$  stators, there is no clear optimum with respect to  $h/C_r$ . For the  $h/C_r = 2.92$  stators, the  $\gamma = 0.27$  and  $\gamma = 0.34$  stators yield larger damping values than the  $\gamma = 0.42$  stator. The absence of clear optima with respect to  $\gamma$  and  $h/C_r$  is significantly different from earlier tests at  $0.51mm$  clearances.

Table 5 provides measured data for  $K_{ef}$ ,  $C_{ef}$ , and  $M_{ef}$  and comparisons to theory for the hole-pattern-stator seals. The comparison between theory and experiment is generally good for  $K_{ef}$  and  $C_{ef}$ . Predictions for  $M_{ef}$  continue to be erratic and small, as compared to measured data, but the correlation is better for hole-pattern stators than smooth stators (compare with table 3).

#### 4.5 Conclusions

The test results presented in this chapter support the following conclusions:

- (a) The test results for pressure gradients in damper seals raise serious questions with respect to our understanding of the correct model for friction factors versus running speed and Reynolds numbers. Neither a Hirs model or a Moody model will correctly predict the measured test data, and the correlation capability drops sharply as  $\gamma$  is increased from 0.34 to 0.42.
- (b) Despite the poor capability of the Hirs formulation for predicting  $\lambda_s$ , the theory of [2] does a fair job of predicting  $K_{ef}$  and  $C_{ef}$ . The prediction accuracy is comparable to that for smooth seals.
- (c) Test results for hole-pattern stators at reduced clearances ( $0.38$  versus  $0.51mm$ ) show no clear optimum of  $C_{ef}$  versus  $h/C_r$ . With  $h/C_r = 2.92$ , a dropoff in  $C_{ef}$  is observed when  $\gamma$  is increased from 0.34 to 0.42.

## CHAPTER V

### TEST RESULTS FOR HELICALLY-GROOVED STATORS

#### 5.1 Introduction

As noted in Chapter I, Kim and Childs developed a theory for helically grooved seals which predicted reductions in the cross-coupled stiffness coefficient for a properly-designed helically-grooved seal. In fact, his theory predicted a reversal in the sign of  $k$ . Test results are presented in this chapter for the helically-grooved stators illustrated in figure 33. The helix angle  $\alpha$  is the principal parameter which is studied, ranging from 0 to 70 degrees. The groove depth and width is held constant. A 30° -helix stator was made with end lands. The same type of test results are presented here as in the preceding chapter for smooth and hole-pattern stators. However, no theoretical predictions of forces are presented because the test and theory are completely at odds with respect to  $C_{ef}$ .

#### 5.2 Friction-Factor Data

Figures 34 through 37 illustrate  $\lambda_c$  for the helically-grooved-stator seals. For the 0° degree stator,  $\lambda_c$  increases with increasing running speed at lower values of  $R_a$ , but decreases with increasing  $\omega$  at higher values of  $R_a$ . Figure 38 illustrates  $\lambda_c$  versus  $R_a$  at 7200 rpm for helix angel 0° through 70°. Observe that  $\lambda_c$  is maximum for the 0°-helix-angle stator at  $R_a$  greater than approximately 175,000. The 15°-helix-angle stator yields the highest value for  $\lambda_c$  for  $R_a$  less than 175,000. Generally speaking,  $\lambda_c$  decreases uniformly as the helix angle increases.

#### 5.3 Leakage Data

Figure 39 illustrates  $C_d^{-1/2}$  for the helically-grooved stators. As expected, leakage increases with increasing helix angles. Also, adding the end seals to the 30° helix stator is seen to reduce leakage. By comparison to figure 8 for smooth seals, helically-grooved stators leak more than smooth seals for  $\alpha$  greater than 30°.

#### 5.4 Dynamic Test Data

Figures 40 through 47 illustrate  $F_r/A$  and  $F_\theta/A$  versus  $\omega$  and  $R_a$  for the eight helically-grooved stators. The  $F_\theta/A$  results of these figures is similar to test results in the previous chapter for smooth and hole-pattern-damper stators. However, much of the  $F_r$  data differ as follows. For the smooth and hole-pattern-damper stators,  $F_r/A$  decreases with increasing  $R_a$  at all speeds. For most of the grooved seals,  $F_r/A$  decreases with increasing  $R_a$  at lower speeds, but increases at high speeds.

Figure 48 illustrates  $\overline{K}_{ef}$  versus  $\Delta P$  for the helically-grooved seals. Generally speaking,  $\overline{K}_{ef}$  first decreases and then increases as the helix angle increases. This result is predicted by the theory of [8]. Adding end lands to the 30° helix-angle stator is seen to increase  $\overline{K}_{ef}$ . A comparison of the helically-grooved-seal test results with the smooth-seal results of figure 12 and the hole-pattern-seal results of figure 30 shows helically-grooved seals to have substantially lower stiffness values for helix angles less than 40°.

Figure 48.  $\bar{K}_{ef}$  versus  $\Delta P$  for the helically-grooved stator seals.

Figure 49 illustrates  $\overline{C}_{ef}$  versus  $\Delta P$  for the helically-grooved-stator seals. Those results indicate the  $\overline{C}_{ef}$  is generally insensitive to changes in the helix angle. The 30° helix-angle stator yields slightly higher damping values than the remaining stators. Adding end lands to the 30° helix-angle stator does not change  $\overline{C}_{ef}$ . A comparison of the results for figures 14, 32, and 50 indicates that the net damping for helically-grooved stators is less than that for either smooth or hole-pattern-damper stators. This result conflicts with the theoretical predictions of reference [8], which predicted a change in sign for  $k$  as the helix angle  $\alpha$  is increased, with a small change in  $C$ . From Eqs. (3) and (25)

$$F_{\theta}/A = k - C\omega$$

$$F_{\theta}/A = -C_{ef}\omega = -C(1 - b_1/2)\omega.$$

The theory of [8] predicts a reversal in sign for  $b_1$ , and a corresponding increase in  $C_{ef}$  for increasing helix angles. The test results generally refute this prediction.

Table 6 contains calculated values for  $K_{ef}$ ,  $C_{ef}$ , and  $M_{ef}$  for the helically-grooved-stator seals which were tested in this study.

### 5.5 Conclusions

The test results of this chapter support the following conclusions with respect to helically-grooved stators:

- (a) Helically-grooved seals leak more as the helix angle increases. Of the seals tested, those with helix angles greater than 30° leaked more than smooth seals.
- (b) The stiffness of helically-grooved seals first decreases and then increases as the helix angle increases. For helix angles less than 40°, helically-grooved seals have substantially lower direct stiffnesses than either smooth or hole-pattern-stator seals.
- (c)  $\overline{C}_{ef}$  for the seals tested is insensitive to helix angle. The 30° -helix stator had slightly better damping characteristics than the other seals.
- (d) Adding end lands to the 30° -helix stator decreased leakage, increased  $\overline{K}_{ef}$ , and had little or no effect on  $\overline{C}_{ef}$ .
- (e) The theory of [8] correctly predicted trends in leakage and  $\overline{K}_{ef}$ ; however, its predictions are wrong for  $\overline{C}_{ef}$ .

## CHAPTER VI

### TEST RESULTS FOR A 30°-HELICALLY-GROOVED STATOR IN AN AIR-SEAL TEST FACILITY

#### 6.1 Introduction

As noted earlier, the liquid-seal test apparatus used in this study is limited in the following respects:

- (a) There is no capability for prerotating the flow entering the seal.
- (b) While a net damping coefficient can be measured, the direct-damping and cross-coupled-stiffness coefficients  $k$  and  $C$  can not be separately identified.

Fortunately, a dynamic, seal-test apparatus and facility have been developed and is available at TAMU which eliminates those shortcomings [12]. Unfortunately, this facility only uses air as a test media. The contents of this chapter concern test results for a 30°-helix, 151.9mm diameter seal tested in air. Dimension's for the stator of this seal are provided in figure 50. A nominally smooth rotor was used with this stator.

Figure 50. Helically Grooved Air Seal

## 6.2 Test Facility

Figures 51 through 53 illustrate the air-seal test apparatus and facility. Observe that the flow can be preswirled immediately before entering the seal. Two preswirl vanes are used to rotate the fluid in the direction of shaft rotation, two are used for prerotation against shaft rotation, and one inlet provides no intentional prerotation.

The housing supporting the shaft is vibrated horizontally while the shaft is rotating. Simultaneous measurements of the seal's rotor motion relative to the stator and seal reaction forces yield data from which the direct and cross-coupled stiffness and damping coefficients can be determined.

The test facility is supplied by a screw compressor which can provide air at pressures up to approximately 7 bars. Since the seal configuration of figure 54 is intended only for liquid applications, only test data at comparatively low pressures and unchoked conditions are examined.

Test results for the helically-grooved stator will be compared to results for a smooth stator and a honeycomb stator. The honeycomb stator has a cell width of  $0.79\text{mm}$  (.031 in) and a cell depth of  $1.47\text{mm}$  (.058 in).

## 6.3 Test Results

Figure 54(a) illustrates the direct and cross-coupled stiffness coefficients  $K_{xx}$ ,  $K_{xy}$  versus  $u_{\theta o} = U_{\theta o}/R\omega$ , the normalized inlet tangential velocity. The results are presented at 3000 CPM and 3.08 bars supply pressure for smooth, honeycomb, and helically-grooved stators. Figure 54 (b) illustrates  $C_{xx}$  and  $K_{xy}/\omega C_{xx}$  versus  $u_{\theta o}$  for the same operating conditions. The data in those figures which is of practical interest concerns positive  $u_{\theta o}$ . A review of these figures supports the following conclusions:

- (a)  $K_{xx}$  is positive for the helically-grooved stator but is much smaller than comparable values for a smooth stator.
- (b)  $K_{xy}$  is smaller for the helically-grooved stator than either the smooth or honeycomb stator.
- (c)  $C_{xx}$  is smaller for the helically-grooved stator than for either the smooth stator or honeycomb stator.
- (d) The whirl-frequency ratio  $K_{xy}/\omega C_{xx}$  is comparable for honeycomb and helically-grooved stators.

Note in comparing these figures that the tangential velocity is highest for the smooth seal, intermediate for the helically-grooved stator, and a minimum for the honeycomb stator. This results is a consequence of the leakage performance of the seals with leakage-rate increasing as one moves from the honeycomb, to helix, to smooth stators. For a given preswirl vane, the inlet tangential velocity goes up with the leakage rate.

Figures 55(a) and (b) provide parallel results for the three stators with running speed increased to 16,000 CPM. Observe that  $K_{xy}$  for the helically-grooved stator is now less than the comparable results for the honeycomb stator. Also, while  $C_{xx}$  continues to be less for the helix stator than the honeycomb stator, the margin has been reduced. The whirl frequency ratio's for the honeycomb and helix stators are about equal for positive  $u_{\theta o}$ .

Figure 53. Inlet guide vane detail.

Figure 55(a).  $K_{xx}$  and  $K_{xy}$  versus  $u_{\theta o}$   
for smooth (1), honeycomb (2), and helix (3) stators at  
16,000 CPM.

Figure 55(b).  $C_{xx}$  and  $K_{xy}/\omega C_{xx}$  versus  $u_{\theta o}$   
for smooth (1), honeycomb (2), and helix (3) stators at  
16,000 CPM.

PRECEDING PAGE BLANK NOT FILMED

Figure 56(a). Test results for  $K_{xx}$  and  $K_{xy}$  versus running speed for smooth (1), honeycomb (2), and helix (3) stators versus running speed for maximum inlet-flow prerotation in the direction of shaft rotation.

Figure 56(b). Test results for  $C_{xx}$  and  $K_{xy}/\omega C_{xx}$  versus running speed for smooth (1), honeycomb (2), and helix (3) stators versus running speed for maximum inlet-flow prerotation in the direction of shaft rotation.

Figures 56(a) and (b) illustrate the rotordynamic coefficients of figure 54 and 55 versus running speed for maximum preswirl in the direction of shaft rotation. Observe that  $K_{xy}$  is smaller for the helix stator than the honeycomb stator and does not increase as rapidly with increasing running speed. Observe in figure 56(b) that  $C_{xx}$  is smaller for the helix stator than the honeycomb stator but increases more rapidly with running speed. Finally, note that the whirl-frequency ratio is generally slightly smaller for the honeycomb stator than the helix stator, except at the highest speed.

Recall in reviewing the results of figure 56 that the helically-grooved stator has a higher leakage rate and accordingly higher inlet tangential velocity. Given that a higher  $u_{\theta o}$  yields higher  $K_{xy}$ , the helix stator suffer an unfair direct comparison in these figures. Even so, the helix stator has comparable rotordynamic-stability performance to the honeycomb stator and its performance is increasing rapidly with speed.

#### 6.4 Conclusions

The test results reported here for smooth, honeycomb, and helically-grooved stators shows comparable performance between honeycomb and helically-grooved stators. From a stability viewpoint, the helically-grooved stator's performance is increasing rapidly with speed. An extrapolation of the data presented here predicts substantially better rotordynamic-stability performance for the helically-grooved stator than a comparable honeycomb stator at higher speeds.

## Chapter VII SUMMARY AND CONCLUSIONS

### 7.1 *Summary and Conclusions*

Test results are presented for the following seals:

- (a) smooth, concentric seals at four clearances (static-test-data only),
- (b) smooth seals at three clearances,
- (c) hole-pattern-damper seals, six configurations, and
- (d) helically-grooved-stator seals, seven helix angles

All of the above seals are tested in a liquid Halon test facility at high Reynolds numbers. In addition, a helically-grooved-stator seal was tested in an air-seal test facility.

An analysis of the test results with comparisons to theoretical predictions supports the following conclusions:

- (a) For seals, the Hirs' friction-factor model is more restricted than had been through previously. Experimentally-derived-Hirs empirical coefficients apply for a reasonable Reynolds number range but are clearly a function of clearance. Further, there are significant differences between measured  $\lambda$  values with centered concentric seals and a seal with the rotor orbiting. Fortunately, the difference between concentric and orbiting-rotor friction factor data is reduced as the radial clearance is reduced.
- (b) Friction factor data for hole-pattern-seal stators frequently deviates from the Hirs model.
- (c) Predictions of stiffness and damping coefficients for hole-pattern-stator seals is generally reasonable.
- (d) Test for the hole-pattern stators at reduced clearances (0.30 mm versus 0.51 mm) show no clear optimum for hole-pattern seals with respect to either hole-area ratio or hole depth to minimum-clearance ratios.
- (e) Tests of these hole-pattern stators show no significant advantage in net damping over smooth seals; however, the seals leak about 30% less than smooth seals.
- (f) Tests of helically-grooved seal stators in Halon show reasonable agreement between theory and prediction for leakage and direct stiffness but poor agreement for the net damping coefficient.
- (g) Tests of a helically-grooved stator in the air seal facility shows superior stability characteristics at high speeds (16,000 rpm) as compared to a honeycomb seal.

### 7.2 *Comments on Friction Factors*

The values of Hirs coefficients which are provided in tables 1, 2, and 4 for the smooth and hole-pattern stators, are not of themselves particularly informative. To provide some perspective, the  $m$  and  $n$  values have been used to calculate friction factors which are illustrated in figure 57. The  $\lambda$  friction factors of this report have been multiplied by a factor of 4 to yield the friction factor values for this figure. The identification on the figure for the smooth stators can best be explained by example. Specifically, .508(S) identifies the

curve belonging to the .508mm radial clearance stator with concentric (static) operating conditions, while .508 (D) identifies the curve belonging to the .508 mm radial clearance stator when tested dynamically, i.e., with an orbiting rotor.

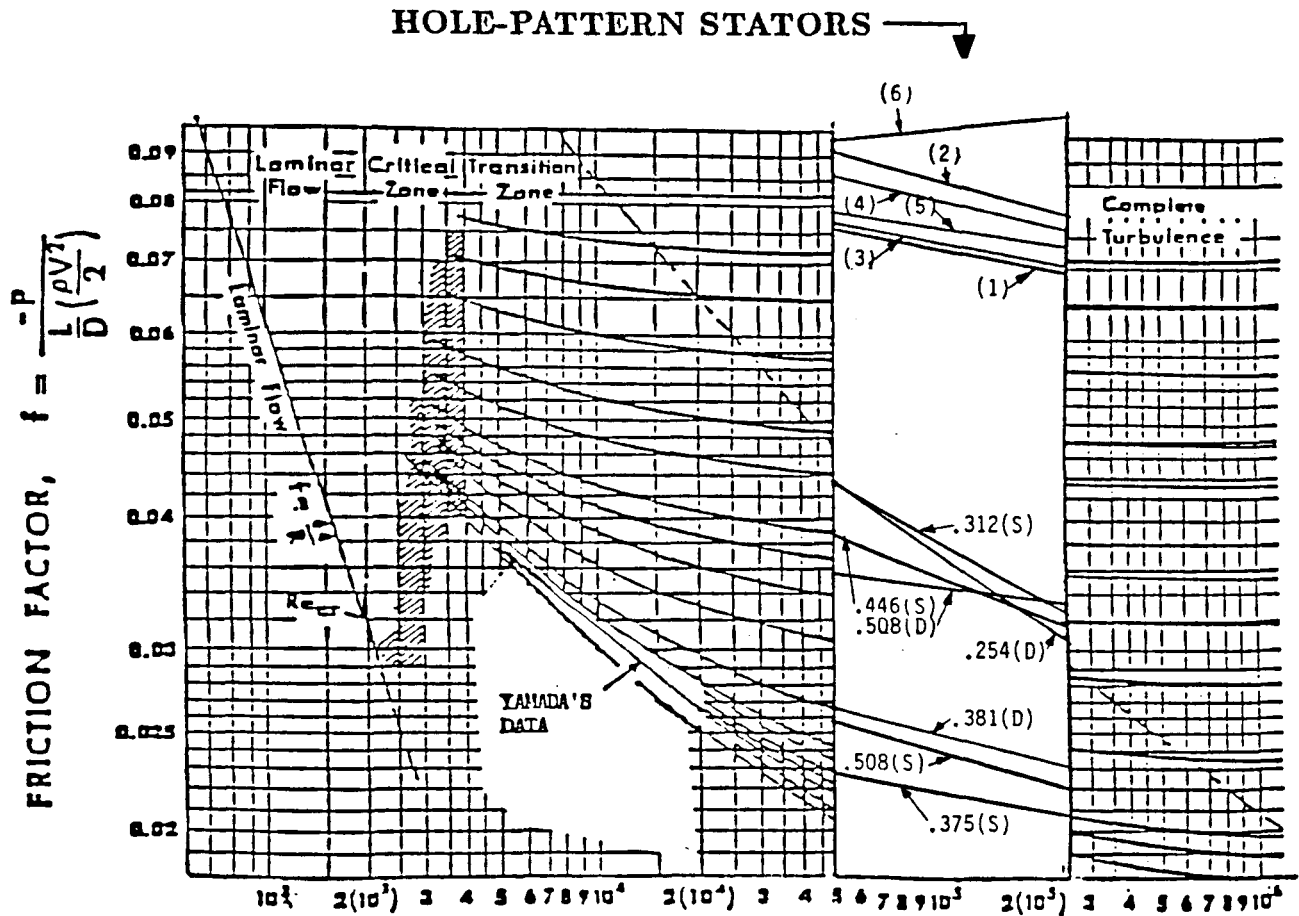

Figure 57. Measured friction-factor data plotted on a Moody diagram.

Observe that the friction-factor data for concentric seals generally proceeds reasonably ( $f$  increases as  $C_r$  decreases) except for the 0.375 (S) curve. The friction factors corresponding to orbiting rotor cases do not proceed as expected since the friction factors are higher for the .508 (D) than the 0.381 (D) curve. Note where the clearances are approximately the same in concentric and orbiting-rotor cases that the dynamic friction factor is always higher, but the difference decreases as the clearance decreases.

The line of the lower left hand side of the turbulent friction factors illustrates Yamada's test-data correlation. Obviously, the "smooth" seals tested in this program have markedly higher friction factors than those measured by Yamada. Differences in surface finishes between the current seals and Yamada's could possibly account for those differences.

Friction-factor curves corresponding to the hole-pattern statots are illustrated at the

top of the Moody diagram. The circled numbers identify the stators. Note that curve has a positive slope corresponding to a positive  $ms$  value in table 4. Obviously, the hole-pattern stators have markedly higher  $\lambda$  values than the smooth stators.

Despite the fact that the analysis for smooth and hole-pattern stators does a reasonably good job of calculating force coefficients, an inspection of figure 57 suggests a discouraging and generally comprehensive failure to model and understand friction factors in seals. Given that the speed and Reynolds-number dependency of  $\lambda$  provides the basic foundation for rotordynamic-coefficient calculation, these are particularly discouraging results. They provide a strong argument for additional and more fundamental measurements of friction-factor data, possibly in a flat-plate tester.
